We conclude that such strong correlations between a single proton and a nuclear system in the shell-model description appear in a very restricted region of the single-particle space. The actual size of this region is most probably too small to be of astrophysical interest. But it points to the fact that single-particle properties, and hence the structure of the nucleus, have a decisive influence on the outcome of nuclear reactions. This might have important implications for the interpretation of various astrophysical reaction rates.
